1. INTRODUCTION

1.1 Background

Pavements are subjected to different stresses during their design lives. A properly designed pavement will perform adequately during its design life, and the distresses will not exceed the allowable limits. A good design is one that provides the expected performance with appropriate economic considerations. One of the factors that leads to premature failure of pavements is moisture sensitivity. The presence of water in pavements can be detrimental if combined with other factors, such as freeze-thaw cycling. Many factors can affect the moisture sensitivity of a mix, and can be divided into three main categories. The first category is the material properties, which include the physical and chemical properties of the asphalt and the aggregates. The second category is the mixture properties, which include asphalt content, film thickness, and the permeability of the mixture (interconnectivity of the air voids). The third category is the external factors; these factors include construction, traffic, and environmental factors (Santucci 2002).

For many years, moisture damage has been a major concern for asphalt technologists. Researchers have been searching for a test that differentiates between good and poor performing asphalt concrete mixtures from stripping potential since the 1920s (Solaimanian et al. 2003). Since the 1920s, it has been known that the problem relates to the loss of adhesion between asphalt and aggregate and the loss of cohesion within the asphalt binder. The challenge has been to find a test that identifies moisture susceptible mixes (Solaimanian et al. 2003). The standard test used to identify the moisture susceptibility of asphalt mixtures is the modified Lottman test (AASHTO T 283). The American Association of State Highway and Transportation Officials (AASHTO) T 283 was used with Marshall mix design methodology and with the development of the Superpave mix design methodology; the same method was adopted with the modification of the compaction method. Although AASHTO T 283 has been used for several years as the standard test for moisture sensitivity, it assists in minimizing the problem but it does not appear to be a very accurate indicator of stripping (Brown et al. 2001). Two of the tests that have the potential to replace indirect tensile strength testing contained within AASHTO T 283 are the dynamic modulus and flow number tests. The advantage of using these two tests is that they are performed by the Asphalt Mixture Performance Tester (AMPT) and are used to predict the mixture performance. An advantage of the dynamic modulus test is that it is the main input for Level 1 design in the *Mechanistic-Empirical Pavement Design Guide* (MEPDG).

1.2 Problem Statement

AASHTO T 283 is the standard test used in the moisture susceptibility evaluation of asphalt mixtures. The results of the test are not very representative of the expected behavior of asphalt mixtures. The dynamic modulus test measures a fundamental property of the mixture. The results of the dynamic modulus test can be used directly in the MEPDG and are considered a very good representation of the expected field performance of the mixture. Further research is still needed to study how the dynamic modulus results are affected by moisture. The flow number test was studied in previous research as a candidate test for moisture-susceptibility evaluation, but the

results of that research were not in favor of using the flow number test in moisture-susceptibility evaluation.

1.3 Objectives

This research has four main objectives. The first objective of this research is to evaluate the usefulness of the dynamic modulus and flow number tests in moisture-susceptibility evaluation. The second objective is to compare the results to those achieved using the AASHTO T 283 test. The third objective is to study the effect of different methods of sample conditioning and testing conditions. The fourth objective of the research is to study the variability in the test results.

1.4 Methodology and Approach

The first objective of this research was achieved by running dynamic modulus and flow number tests on 16 field-procured/laboratory-compacted specimens at different conditioning/test conditions. The dynamic modulus test was performed on unconditioned samples and samples conditioned by moisture saturation with a freeze-thaw cycle at various frequencies and test temperatures. The same samples were then tested for flow number. The second objective will be achieved by testing samples using the AASHTO T 283 procedure and comparing the results to those achieved using the dynamic modulus and flow number tests. To fulfill the third objective, flow number testing was performed on samples with four different conditioning/testing conditions. The four conditions are unconditioned without water submersion, moisture saturated with water submersion testing, moisture saturation with freeze/thaw conditioning without water submersion testing, and moisture saturation with freeze/thaw conditioning and with water submersion testing. Five of the 16 mixes were tested under a fifth condition, which is unconditioned with water submersion to study the effect of the water submersion of the samples. The comparison between the results of the unconditioned set of samples and the conditioned set was used to evaluate the moisture damage. The fourth objective was achieved by running a comprehensive statistical analysis of the laboratory results.

1.5 Hypothesis

The laboratory testing was performed under two main hypotheses that were tested statistically.

- The first hypothesis was that the dynamic modulus test results are directly affected by moisture conditioning of the samples. The effect of moisture was studied on the dynamic modulus value, the phase angle, and the combined effect of dynamic modulus and phase angle represented by the loss modulus and the storage modulus.
- The second hypothesis was that although the flow number test is not recommended for the evaluation of the moisture susceptibility of an asphalt mixture, it can still have value by investigating other parameters that can be calculated from the test results.

Some additional hypotheses were addressed by answering the following questions:

- Which test procedure better simulates moisture damage: AASHTO T 283, dynamic modulus, or flow number?
- Do these hot mix asphalt (HMA) mixture tests rank the HMA mixtures the same?
- Is there a difference between the results from the different conditioning/testing conditions?

1.6 Significance of Work

The significance of this research work is that it employs tests that are commonly used in the asphalt industry and uses them to evaluate the moisture susceptibility of the mixes. The research also examines the tests from a perspective different from in previous research.

1.7 Report Organization

This report is divided into eight chapters. The first chapter is an introduction, which gives a brief background about the topic and a problem statement. In this chapter, the research objectives and hypothesis are presented, the methodology is outlined, and the significance of the research is presented. Chapter 2 of this report discusses past research and studies that have been related to moisture damage or moisture susceptibility. Included is a brief description of the research conducted along with major findings of the study that directly apply to this research. Chapter 3 outlines the experimental plan and procedures used to sample, prepare, and test specimens for this research. Chapter 4 presents the results of the dynamic modulus testing. Chapter 5 presents the results of the flow number testing with a selection of the parameter that best represents the moisture susceptibility of the mixes. Chapter 6 presents the results from the AASHTO T 283 testing. Chapter 7 presents a statistical analysis that compares the different tests and recommends the most appropriate test. Chapter 8 presents the summary, conclusions, and recommendations for further research.

2. LITERATURE REVIEW

2.1 Moisture Susceptibility

The presence of water in an asphalt pavement is unavoidable. Several sources can lead to the presence of water in the pavement. Water can infiltrate the pavement from the surface via cracks in the surface of the pavement, via the interconnectivity of the air-void system or cracks, from the bottom due to an increase in the ground water level, or from the sides. Inadequate drying of aggregate during the mixing process can lead to the presence of water in the pavement as well (Santucci 2002).

Moisture damage can be defined as the loss of strength and durability in asphalt mixtures due to the effects of moisture (Little and Jones 2003). Premature failure may result due to stripping when critical environmental conditions act together with poor and/or incompatible materials and traffic (Brown et al. 2001). Moisture susceptibility is a problem that typically leads to the stripping of the asphalt binder from the aggregate, and this stripping makes an asphalt concrete mixture ravel and disintegrate (Brown et al. 2001). Moisture damage can occur due to three main mechanisms: (1) loss of cohesion of the asphalt film, (2) failure of the adhesion between the aggregate particles and the asphalt film, and (3) degradation of aggregate particles due to freezing (Brown et al. 2001). There are six contributing processes that have been attributed to causing moisture damage in asphalt mixtures: detachment, displacement, spontaneous emulsification, pore-pressure-induced damage, hydraulic scour, and environmental effects (Little and Jones 2003; Roberts et al. 1996). Not one of the above factors necessarily works alone in damaging an asphalt concrete pavement, as they can work in a combination of the processes.

2.2 Causes of Moisture Damage

Moisture damage can be defined as the loss of strength and durability in asphalt mixtures due to the effects of moisture (Little and Jones 2003). Moisture can damage HMA in two ways: (1) loss of bond between asphalt cement or mastic and fine and coarse aggregate or (2) weakening of mastic due to the presence of moisture. There are six contributing factors that have been attributed to causing moisture damage in HMA: detachment, displacement, spontaneous emulsification, pore-pressure-induced damage, hydraulic scour, and environmental effects (Roberts et al. 1996; Little and Jones 2003). Not one of the above factors necessarily works alone in damaging an HMA pavement, as they can work in a combination of the processes. Therefore, a need exists to examine the adhesive interface between aggregates and asphalt and the cohesive strength and durability of mastics (Graff 1986; Roberts et al. 1996; Little and Jones 2003; Cheng et al. 2003). A loss of the adhesive bond between aggregate and asphalt can lead to stripping and raveling, while a loss of cohesion can lead to a weakened pavement that is susceptible to premature cracking and pore pressure damage (Majidzadeh and Brovold 1968; Kandhal 1994; Birgission et al. 2003). A brief discussion about these factors is presented next.

2.2.1 Detachment

Detachment is the separation of an asphalt film from an aggregate surface by a thin film of water without an obvious break in the film (Majidzadeh and Brovold 1968). Adhesive bond energy theory explains the rationale behind detachment. In order for detachment not to happen, a good bond must develop between asphalt and aggregate; this is known as wettability (Scott 1978). As free surface energy of adhesion or surface tension decreases, the bond between the aggregate and asphalt increases. Consider a three-phase system of aggregate, asphalt, and water. Water reduces the surface energy of a system because aggregate surfaces have a stronger preference for water than asphalt (Majidzadeh and Brovold 1968). Cheng et al. (2002) calculated adhesive bond strengths by measuring the surface energies of components, the asphalt-aggregate interface, in the presence of water, and when under dry conditions.

2.2.2 Displacement

Displacement can occur at a break in the asphalt film at the aggregate surface where water can intrude and displace asphalt from aggregate (Fromm 1974; Tarrer and Wagh 1991). The break in an asphalt film can come from an incomplete coating of aggregate particles, inadequate coating at sharp edges of aggregates, or pinholes in the asphalt film. Chemical reaction theory can be used to explain stripping as a detachment mechanism according to Scott (1978). The pH of water at the point of film rupture can increase the process of displacement thereby increasing the separation of asphalt from aggregate (Scott 1978; Tarrer and Wagh 1991; Little and Jones 2003).

2.2.3 Spontaneous Emulsification

Spontaneous emulsification occurs due to inverted emulsion of water droplets in asphalt cement (Little and Jones 2003). The water diffuses into asphalt cement, thereby attaching itself to an aggregate and causing a separation between asphalt and aggregate. A loss of adhesive bond occurs between asphalt and aggregate. Clays and asphalt additives can further aggravate the emulsification process (Scott 1978; Fromm 1974; Asphalt Institute 1981).

2.2.4 Pore Pressure

Pore pressure can develop in an HMA pavement due to entrapped water or water that traveled into air-void systems in vapor form (Little and Jones 2003; Kandhal 1994). The pore pressure in an HMA pavement can increase due to repeated traffic loading and/or increases in temperature. If an HMA pavement is permeable, water can escape and flow out. However, if it is not permeable, the resulting increased pore pressure may surpass the tensile strength of an HMA and strips asphalt film from an aggregate, causing microcracking (Majidzadeh and Brovold 1968; Little and Jones 2003). Microcracking can also be seen in a mastic under repeated loading, thus resulting in an adhesive and/or cohesive failure (Little and Jones 2003). The rate of microcracking is accelerated by an increase in pore pressure and the presence of water in HMA. The air-void system, or permeability of a pavement, is an important property in order to control pore pressure in an HMA pavement.

2.2.5 Hydraulic Scour

Hydraulic scour (stripping) occurs at a pavement surface and is a result of repeated traffic tires on a saturated pavement surface. Water is sucked into a pavement by tire rolling action (Little and Jones 2003). Hydraulic scour may occur due to osmosis or pullback (Fromm 1974). Osmosis is the movement of water molecules from an area of high concentration to an area of low concentration. In the case of HMA, osmosis occurs in the presence of salts or salt solutions in aggregate pores. The movement of these molecules creates a pressure gradient that sucks water through the asphalt film (Mack 1964; Little and Jones 2003). The salt solution moves from an area of high concentration to an area of low concentration. Cheng et al. (2002) showed that there is a considerable amount of water that diffuses through the asphalt cement and that asphalt mastics can hold a significant amount of water.

2.2.6 Environmental Effects

Factors such as temperature, air, and water have deleterious effects on the durability of HMA (Terrel and Shute 1989; Tandon et al. 1998). Other mechanisms, such as a high water table, freeze/thaw cycles, and aging of binder or HMA, can affect the durability of HMA (Scherocman et al. 1986; Terrel and Al-Swailmi 1992,; Choubane et al. 2000). Other considerations, such as construction (segregation and raveling) and traffic, are also important.

2.3 Adhesion Theories

Four theories are used to describe the adhesion characteristics between asphalt and aggregate. The four theories are chemical reaction, surface energy, molecular orientation, and mechanical adhesion (Terrel and Al-Swailmi 1992). Surface tension of asphalt cement and aggregate, chemical composition of asphalt and aggregate, asphalt viscosity, surface texture of aggregates, aggregate porosity, aggregate clay/silt content, aggregate moisture content, and temperature at the time of mixing with asphalt cement and aggregate are material properties that affect adhesion (Terrel and Al-Swailmi 1992). A brief explanation of the four theories is presented in the following sections.

2.3.1 Chemical Reaction

The reaction of acidic and basic components of asphalt and aggregate form water insoluble compounds that resist stripping (Terrel and Al-Swailmi 1992). A chemical bond forms that allows an asphalt-aggregate mix to resist stripping. The use of basic instead of acidic aggregates can lead to better adhesion of asphalt to aggregates (Terrel and Al-Swailmi 1992).

2.3.2 Surface Energy and Molecular Orientation

Surface energy can be described by how well asphalt or water coats aggregate particles (Terrel and Al-Swailmi 1992). Water is a better wetting agent because of its lower viscosity and lower surface tension than asphalt (Little and Jones 2003). Using surface energy theory to calculate

adhesive bond energies between asphalt and aggregate and cohesive strength of a mastic is rather complex and will be discussed further under “Tests on Loose Mixture and Asphalt Binders” in Section 2.5.1.

The structuring of asphalt molecules at an asphalt-aggregate interface is molecular orientation. The adhesion between asphalt and aggregate is facilitated by a surface energy reduction at the aggregate surface where asphalt is adsorbed onto a surface (Terrel and Al-Swailmi 1992; Little and Jones 2003).

2.3.3 Mechanical Adhesion

Mechanical adhesion is a function of various aggregate physical properties, such as surface texture, porosity, absorption, surface coatings, surface area, and particle size (Terrel and Al-Swailmi 1992; Little and Jones 2003). In short, an aggregate with desirable properties that will not show a propensity to moisture damage within an HMA is wanted.

2.4 Cohesion Theories

According to Little and Jones (2003), cohesion is developed in a mastic and is influenced by the rheology of the filled binder. The cohesive strength of a mastic is a function of the interaction between the asphalt cement and mineral filler, not just of the individual components alone. The cohesive strength of a mastic is weakened due to the presence of water through increased saturation and void swelling or expansion (Terrel and Al-Swailmi 1992; Little and Jones 2003). Cheng et al. (2002) showed that the cohesive strength can be damaged in various mixtures by the diffusion of water into asphalt mastics.

2.5 Tests for Determining Moisture Susceptibility

Due to the detrimental effect of moisture damage, it is important to test the susceptibility of an asphalt mixture to moisture damage. Many tests are available; some are tests for asphalt binder, while others are for asphalt mixes. The tests for asphalt mixes are divided into tests for loose mixes and tests for compacted mixes. Despite the availability of tests for moisture susceptibility, none of them provides high correlation with field performance.

2.5.1 Tests on Loose Mixture and Asphalt Binders

Moisture-susceptibility tests that are performed on loose mixtures are conducted on asphalt-coated particles in the presence of water. The two main advantages of these tests are the testing simplicity and inexpensive nature in comparison to compacted-specimen test expenses. Another significant advantage is the use of simple equipment and procedures to conduct experiments (Solaimanian et al. 2003). The tests are summarized in Table 2-1.

Table 2-1. Moisture-sensitivity tests on loose samples (Solaimanian et al. 2003)

Pneumatic Pull-Off			Youtcheff and Aurilio (1997)

*No longer available as ASTM standard.

2.5.1.1 Methylene Blue Test

The methylene blue test is used to identify “dirty” aggregates that contain harmful clays and dust (Solaimanian et al. 2003). If dust or harmful clays are on aggregate particles, they affect the adhesion of the asphalt binder to the aggregate particles, and thus, a potential for stripping may occur in the HMA. This test is used to identify aggregates that contain clays or dust. Since no asphalt is used, this test cannot measure a potential for HMA stripping.

2.5.1.2 Static Immersion Test (AASHTO T 182)

A sample of HMA mix is cured for 2 hours at 60°C before being placed in a jar and covered with water. The jar is left undisturbed for 16 to 18 hours in a water bath at 25°C. Again, the amount of stripping is visually estimated by looking at the HMA sample in the jar. The results of this test are given as either less than or greater than 95% of an aggregate surface is stripped (Solaimanian et al. 2003).

2.5.1.3 Dynamic Immersion Test

The dynamic immersion test (DIM) is similar to the static immersion test, but the DIM test is used to accelerate the stripping effect. Loose mixture is agitated in a jar filled with water in order to produce a dynamic effect (Solaimanian et al. 2003). Again, the results show that as the period of agitation increases, the amount of stripping increases; however, the tests fail to simulate pore pressure and traffic, which is the case with all loose mixture tests.

2.5.1.4 Film Stripping Test (California Test 302)

The film stripping test is a modified version of the static immersion test (AASHTO T 182). A loose mixture of asphalt-coated aggregates is aged in an oven at 60°C for 15 to 18 hours before being placed in a jar filled with water to cool. The jar with loose mix is rotated at 35 revolutions per minute (rpm) for 15 minutes to stir up the mix. Baffels in a jar stir up the mix to accelerate the stripping process. After 15 minutes, the sample is removed, the loose mixture is viewed under a fluorescent light, and the percentage of stripping is estimated. The results of this test are given in percentage of total aggregate surface stripped (Solaimanian et al. 2003).

2.5.1.5 Rolling Bottle Test

Isacson and Jorgenson developed the Rolling Bottle Test in Sweden in 1987. The test is similar to the DIM in that aggregate chips are coated in asphalt and placed in a glass jar filled with water. The glass jar is rotated to agitate loose HMA. A visual inspection is completed to note how much asphalt has been stripped from aggregates (Solaimanian et al. 2003).

2.5.1.6 Chemical Immersion Test

A loose sample of asphalt-coated aggregate is placed in boiling water while increasing the amount of sodium carbonate. The concentration of sodium carbonate is slowly increased until stripping occurs and the concentration of sodium carbonate is recorded. The recorded number is referred to as the Riedel and Weber (R&W) number. Zero refers to distilled water, 1 refers to 0.41 g of sodium carbonate, and 9 refers to the highest concentration of sodium carbonate, or 106 g. The sample is removed from the water and sodium carbonate solution and examined for stripping (Solaimanian et al. 2003).

2.5.1.7 Boiling Water Test

Several versions of a boiling water test have been developed by various state agencies, including one from the Texas State Department of Highways and Public Transportation (Kennedy et al. 1983 and 1984). A visual inspection of stripping is made after the sample has been subjected to the action of water at an elevated temperature for a specified time (Kennedy et al. 1983 and 1984; Solaimanian et al. 2003). This test identifies mixes that are susceptible to moisture damage, but it does not account for mechanical properties or the effects of traffic (Kennedy et al. 1983 and 1984; Solaimanian et al. 2003).

2.5.1.8 Surface Reaction Test

A major problem with the tests previously presented is the dependence on visual observation for identifying stripping. The surface reaction test allows a researcher to quantify the level of stripping on loose asphalt mixtures. This procedure was developed by Ford et al. (1974). The surface reaction test evaluates the reactivity of calcareous or siliceous aggregates and reaction response to the presence of highly toxic and corrosive acids. As part of the chemical reaction, gas

is emitted, which generates a pressure, and this pressure is proportional to the aggregate surface area (Solaimanian et al. 2003). This test is based on the premise that different levels (severity) of stripping result in exposed surface areas of aggregates.

2.5.1.9 Net Adsorption Test

The Strategic Highway Research Program (SHRP) developed a test called the net adsorption test (NAT) in the early 1990s that is documented under SHRP-A-341 (Curtis et al. 1993). This test examines the asphalt-aggregate system and its affinity and compatibility (Solaimanian et al. 2003). In addition, this test also evaluates the sensitivity of the asphalt-aggregate pair. In terms of other tests, the NAT yields mixed results when compared to the indirect tensile test with moisture-conditioned specimens (Solaimanian et al. 2003). The NAT was modified by researchers at the University of Nevada–Reno, and the results were correlated with the environmental conditioning chamber (ECS) (Scholz et al. 1994). According to SHRP-A-402, the water sensitivity of a binder as estimated by NAT showed little or no correlation to wheel-tracking tests on the mixes (Scholz et al. 1994).

2.5.1.10 Wilhelmy Plate Test and Universal Sorption Device

Researchers at Texas A&M University have led in investigating cohesive and adhesive failure models based on surface energy theory and a moisture diffusion model based on results from the Universal Sorption Device (USD) (Cheng et al. 2003). The principle behind surface energy theory is that the surface energy of an asphalt and aggregate is a function of the adhesive bond between asphalt and aggregate and the cohesive bonding within asphalt (Solaimanian et al. 2003). The Wilhelmy plate is used to determine the surface free energy of an asphalt binder where the dynamic contact angle is measured between asphalt and a liquid solvent (Cheng et al. 2003; Solaimanian et al. 2003). The USD test is used to determine the surface free energy of an aggregate (Cheng et al. 2003; Solaimanian et al. 2003). The surface free energy is then used to compute the adhesive bond between an asphalt binder and aggregate. Cheng et al. (2002) showed that the adhesive bond per unit area of aggregate is highly dependent on the aggregate and asphalt surface energies. Also, this test shows that stripping occurs because the affinity of an aggregate for water is much greater than that for asphalt, thus weakening the bond at the asphalt-aggregate interface (Cheng et al. 2002).

Current research at Texas A&M University (Bhasin et al. 2006; Masad et al. 2006) has shown that the moisture resistance of asphalt-aggregate combinations depends on surface energies of asphalt binders and aggregates. The factors considered are film thickness, aggregate shape characteristics, surface energy, air-void distribution, and permeability. The ratio of adhesive bond energy under dry conditions to adhesive bond energy under wet conditions can be used to identify moisture-susceptible asphalt-aggregate combinations, and a ratio of 0.80 should be used as a criterion to separate good and poor combinations of materials. Dynamic mechanical analysis tests were conducted to evaluate a mixture's ability to accumulate damage under dry and moist conditions. A mechanistic approach using a form of the Paris law was used for the evaluation of moisture damage. The mechanical properties are influenced by aggregate gradation, aggregate

shape characteristics, and film thickness. This approach captures the influence of moisture on crack growth and is able to distinguish good and poor performing HMA mixtures.

2.5.2 Tests on Compacted Mixtures

Tests conducted on compacted mixtures include laboratory-compacted specimens, field cores, and/or slabs compacted in a laboratory or taken from the field. Table 2-2 provides moisture-sensitivity tests that have been performed on compacted specimens. From these tests, physical and fundamental/mechanical properties can be measured while accounting for traffic/water action and pore pressure effects (Solaimanian et al. 2003). Some disadvantages of conducting tests on compacted mixtures are the expensive laboratory testing equipment, longer testing times, and potentially labor-intensive test procedures.

Table 2-2. Moisture-sensitivity tests on compacted samples (Solaimanian et al. 2003)

Test Method	ASTM	AASHTO	Other
Moisture Vapor Susceptibility			California Test 307 Developed in late 1940's
Immersion-Compression	D1075	T165	ASTM STP 252 (Goode 1959)
Marshal Immersion			Stuart 1986
Freeze/thaw Pedestal Test			Kennedy et al. 1982
Original Lottman Indirect Tension			NCHRP Report 246 (Lottman 1982); Transportation Research Record 515 (1974)
Modified Lottman Indirect Tension		T283	NCHRP Report 274 (Tunnicliff and Root 1984), Tex 531-C
Tunnicliff-Root	D4867		NCHRP Report 274 (Tunnicliff and Root 1984)
ECS with Resilient Modulus			SHRP-A-403 (Al-Swailmi and Terrel 1994)
Hamburg Wheel Tracking			Tex-242-F
Asphalt Pavement Analyzer			Pavement Technology Inc., Operating Manual
ECS/SPT			NCHRP 9-34 (2002-03)
Multiple Freeze/thaw			No standard exists

2.5.2.1 Immersion-Compression Test

The immersion-compression test (ASTM D 1075 and AASHTO T 165-155) is among the first moisture-sensitivity tests developed based on testing 100 mm diameter compacted specimens.

This test consists of compacting two groups of specimens: a control group and a moisture-conditioned group at an elevated temperature (48.8°C water bath) for four days (Roberts et al. 1996). The compressive strength of the conditioned and control group are then measured (Roberts, et al. 1996). The average strength of the conditioned specimens over that of the control specimens is a measure of strength lost due to moisture damage (Solaimanian et al. 2003). Most agencies specify a minimum retained compressive strength of 70%. The test details are presented in ASTM Special Technical Publication 252 (Goode 1959).

2.5.2.2 Marshall Immersion Test

The procedure for producing and conditioning two groups of specimens is identical to the immersion-compression test. The only difference is that the Marshall stability test is used as the strength parameter as opposed to the compression test (Solaimanian et al. 2003). There is no documented number for the minimum retained Marshall stability.

2.5.2.3 Moisture Vapor Susceptibility

The moisture vapor susceptibility test was developed by the California Department of Transportation (California Test Method 307). A California kneading compactor is used to compact two specimens. The compacted surface of each specimen is sealed with an aluminum cap, and a silicone sealant is applied to prevent the loss of moisture (Solaimanian et al. 2003). After the specimens have been conditioned at an elevated temperature and suspended over water, testing of the specimens commences. The Hveem stabilometer is used to test both dry and moisture-conditioned specimens. A minimum Hveem stabilometer value is required for moisture-conditioned specimens, which is less than that required for dry specimens used in the mix design (Solaimanian et al. 2003).

2.5.2.4 Repeated Pore Water Pressure Stressing and Double-Punch Method

The repeated pore water pressure stressing and double-punch method was developed by Jimenez at the University of Arizona (1974). This test accounts for the effects of dynamic traffic loading and mechanical properties. In order to capture the effects of pore water pressure, the specimens are conditioned by a cyclic stress under water. After the specimen has undergone the pore pressure stressing, the tensile strength is measured using the double-punch equipment. Compacted specimens are tested through steel rods placed at either end of the specimen in a punching configuration.

2.5.2.5 Original Lottman Test

The original Lottman test was developed at the University of Idaho by Robert Lottman (1978). The laboratory procedure consists of compacting three sets of 100 mm diameter by 63.5 mm Marshall specimens to be tested dry or under accelerated moisture conditioning (Lottman et al. 1974). The following are laboratory conditions for each of the groups:

- Group 1: Control group, dry
- Group 2: Vacuum saturated with water for 30-minutes
- Group 3: Vacuum saturation followed by freeze cycle at -18°C for 15 hours and then subjected to a thaw at 60°C for 24 hours (Lottman et al. 1974).

After the conditioning phase, the indirect tensile equipment is used to conduct tensile resilient modulus and tensile strength of conditioned and dry specimens. All specimens are tested at 13°C or 23°C at a loading rate of 1.65 mm/min. The severity of moisture damage is based on a ratio of conditioned to dry specimens (tensile strength ratio [TSR]) (Lottman et al. 1974; Lottman 1982). A minimum TSR value of 0.70 is recommended (NCHRP 246). Laboratory-compacted specimens were compared to field cores and plotted against each other on a graph. The laboratory and field core specimens line up fairly close to the line of equality.

2.5.2.6 Modified Lottman Test (AASHTO T 283)

AASHTO T 283, “Resistance of Compacted Bituminous Mixture to Moisture Induced Damage,” is the most commonly used test method for determining moisture susceptibility of HMA. This test is similar to the original Lottman test with only a few exceptions, as follows:

- Two groups, control versus moisture conditioned
- Vacuum saturation until a saturation level of 70% to 80% is achieved
- Test temperature and loading rate changed to 50 mm/min at 25°C.

A minimum TSR value of 0.70 is recommended, but many agencies specify a TSR value of 0.80 (Roberts et al. 1996). AASHTO T 283 was adopted by the Superpave system as the moisture test method of choice even though AASHTO T 283 was developed for the Marshall mixture design. State highway agencies have reported mixed results when using AASHTO T 283 and comparing the results to field performance (Stroup-Gardiner and Epps 1992; Solaimanian et al. 2003). NCHRP Project 9-13 looked at different factors affecting test results, such as types of compaction, diameter of specimen, degree of saturation, and freeze/thaw cycles. Conclusions from looking at the previously mentioned factors can be seen in the NCHRP Report 444 (Epps et al. 2000). The researchers concluded that either AASHTO T 283 does not evaluate moisture susceptibility or the criterion, TSR, is incorrectly specified. NCHRP 9-13 examined mixtures that have historically been moisture susceptible and ones that have not. The researchers also examined the current criteria using Marshall and Hveem compaction. A recent study at the University of Wisconsin found that no relationship exists between TSR and field performance in terms of pavement distress index and moisture damage (surface raveling and rutting) (Kanitpong and Bahia 2006). Additional factors, such as production and construction, asphalt binder, and gradation, play important roles, whereas mineralogy does not appear to be an important factor in relation to pavement performance.

AASHTO T 283 was developed based on 100 mm Marshall-compacted specimens. With the transition from 100 mm Marshall-compacted specimens to 150 mm Superpave-compacted specimens, the standard allowed the use of either 150 or 100 mm samples, and the requirements

remained the same. Research was done to investigate the effect of the different sample sizes. It was discovered that three freeze/thaw cycles for conditioning are needed when using specimens created using 150 mm Superpave specimens (Bausano et al. 2006; Kvasnak 2006). However, to continue using one freeze/thaw cycle and maintain the same probability level as attained with a TSR value for 0.80 for 100 mm Marshall-compacted specimens, a TSR value of 0.87 and 0.85 should be used for 150 mm and 100 mm Superpave-compacted specimens, respectively. A 0.80 TSR for 150 mm Superpave specimens would correspond to a TSR ratio of 0.80 for 100 mm Marshall specimens (Bausano et al. 2006; Kvasnak 2006).

2.5.2.7 Texas Freeze/Thaw Pedestal Test

The water-susceptibility test was developed by Plancher et al. (1980) at Western Research Institute but was later modified into the Texas freeze/thaw pedestal by Kennedy et al. (1983). Even though this test is rather empirical in nature, it is fundamentally designed to maximize the effects of bond and to minimize the effects of mechanical properties, such as gradation, density, and aggregate interlock, by using a uniform gradation (Kennedy et al. 1983). An HMA briquette is made according to the procedure outlined by Kennedy et al. (1983). The specimen is then placed on a pedestal in a jar of distilled water and covered. The specimen is subjected to thermal cycling and inspected each day for cracks. The number of cycles to induce cracking is a measure of the water susceptibility (Kennedy et al. 1983). The benefits of running this test are that some key failures can be seen:

- Bond failure at the asphalt-aggregate interface (stripping)
- Fracture of the thin asphalt films bonding aggregate particles (cohesive failure) by formation of ice crystals (Solaimanian et al. 2003)

2.5.2.8 ASTM D 4867 (Tunnickliff-Root Test Procedure)

ASTM D 4867, “Standard Test Method for Effect of Moisture on Asphalt Concrete Paving Mixtures,” is comparable to AASHTO T 283. The only difference between AASHTO T 283 and ASTM D 4867 is that the curing of loose mixture at 60°C in an oven for 16 hours is eliminated in ASTM D 4867. A minimum TSR of 0.70 to 0.80 are specified by highway agencies (Roberts et al. 1996).

2.5.2.9 Hamburg Wheel-Tracking Device (HWTD)

The Hamburg Wheel-Tracking Device (HWTD) was developed by Esso A.G. and is manufactured by Helmut-Wind, Inc., of Hamburg, Germany (Aschenbrener et al. 1995; Romero and Stuart 1998). Two samples of HMA beams with each beam having a geometry of 260 mm wide, 320 mm long, and 40 mm thick. This device measures the effects of rutting and moisture damage by running a steel wheel over the compacted beams immersed in hot water (typically 50°C) (Aschenbrener et al. 1995). The steel wheel is 47 mm wide and applies a load of 705 N while traveling at a maximum velocity of 340 mm/sec in the center of the sample. A sample of HMA is loaded for 20,000 passes or until 20 mm of permanent deformation occurs (Aschenbrener et al. 1995). Some important results the HWTD gives are:

- Postcompaction consolidation: deformation measured after 1,000 wheel passes
- Creep slope: number of wheel passes to create a 1 mm rut depth due to viscous flow
- Stripping slope: inverse of the rate of deformation in the linear region of the deformation curve
- Stripping inflection point: number of wheel passes at the intersection of the creep slope and stripping slope (Aschenbrener et al. 1995)

2.5.2.10 Asphalt Pavement Analyzer (APA)

The Asphalt Pavement Analyzer (APA) is a type of loaded wheel test. Rutting, moisture susceptibility, and fatigue cracking can all be examined with an APA. The predecessor to the APA is the Georgia Loaded Wheel Tester (GLWT). Similar to the GLWT, an APA can test either cylindrical or rectangular specimens. Using either specimen geometry, the conditioned and unconditioned samples are subjected to a steel wheel that transverses a pneumatic tube, which lies on top of an asphalt sample. As the wheel passes back and forth over the tube, a rut is created in a sample. Numerous passes lead to a more defined rut and, eventually, stress fractures can begin to manifest as cracks. Modeling these ruts and cracks helps to predict how different combinations of aggregate and binder for given criteria, such as temperature and loading, will react under varying circumstances. The conditioning of a sample is based on the characteristic an APA is testing. One of the main differences between an APA and a GLWT is an APA's ability to test samples under water as well as in air. Testing submerged samples allows researchers to examine moisture susceptibility of mixes (Cooley et al. 2000).

APA results are comparable to field data. A study that compared WesTrack, a full-scale test track, data with APA results found a strong relationship between field and laboratory data (Williams and Prowell 1999). An additional study at the University of Tennessee revealed that an APA sufficiently predicted the potential for rutting of 30 HMAs commonly used in Tennessee (Jackson and Baldwin 1999). A study using the APA showed that there is a strong relationship between water absorbed and APA test data. When the APA results were compared to those of AASHTO T 283, there were no strong relationships between TSR results and APA test results. The variability of the rut depth data was high; conduct the recommended study using at least three replicates (Kvasnak 2006).

To test moisture-susceptible HMA samples, specimens are created in the same manner as the specimens for testing rutting potential without moisture. The samples are placed in an APA, which has an inner box that can be filled with water. The samples are completely submerged at all times during testing; therefore, effects of evaporation do not need to be taken into account. The water bath and air in the chamber are heated to the same desired test temperature.

2.5.2.11 Flexural Fatigue Beam Test with Moisture Conditioning

Moisture damage has been known to accelerate fatigue damage in pavements. Therefore, conditioning of flexural fatigue beams was completed by Shatnawi et al. (1995). Laboratory-

compacted beams were prepared from HMA sampled at jobs, and corresponding field fatigue beams were cut from the pavement. The conditioning of the beams was as follows:

- Partial vacuum saturation of 60% to 80%
- Three repeated five-hour cycles at 60°C followed by four hours at 25°C while remaining submerged
- One five-hour cycle at -18°C (Shatnawi et al. 1995).

The specimens are then removed from a conditioning chamber and tested according to AASHTO T 321. Initial stiffness and fatigue performance were affected significantly by conditioning the specimens (Shatnawi et al. 1995).

2.5.2.12 Environmental Conditioning System (ECS)

The ECS was developed by Oregon State University as part of the SHRP-A-403 and later modified at Texas Technological University (Alam et al. 1998). The ECS subjects a membrane-encapsulated HMA specimen that is 102 mm in diameter by 102 mm in height to cycles of temperature, repeated loading, and moisture conditioning (SHRP-A-403 1992; Al-Swailmi and Terrel 1992a; Al-Swailmi and Terrell 1992b; Terrel and Al-Swailmi 1993). Some important fundamental material properties are obtained from using an ECS. These properties are resilient modulus (M_R) before and after conditioning, air permeability, and a visual estimation of stripping after a specimen has been split open (SHRP-A-403 1992). One of the significant advantages of using an ECS is the ability to influence the HMA specimens to traffic loading and the resulting effect of pore water pressure, which is close to field conditions (Solaimanian et al. 2003). The downfall of the test is that it does not provide a better relationship to field observation than what was observed using AASHTO T 283. Also, AASHTO T 283 is much less expensive to perform and less complex than the ECS.

2.5.2.13 ECS/Simple Performance Test Procedures

As a result of NCHRP Projects 9-19, 9-29, and 1-37 (NCHRP reports 465, 513, and MEPDG), new test procedures, such as asphalt mixture performance tests (AMPTs), are being evaluated. According to Witczak et al. (2002), an AMPT is defined as “A test method(s) that accurately and reliably measures a mixture response or characteristic or parameter that is highly correlated to the occurrence of pavement distress (e.g., cracking and rutting) over a diverse range of traffic and climatic conditions.” The mechanical tests being looked at are the dynamic modulus $|E^*|$, repeated axial load (F_N), and static axial creep tests (F_T). These tests are conducted at elevated temperatures to determine a mixture’s resistance to permanent deformation. The dynamic modulus test is conducted at an intermediate and lower test temperature to determine a mixture’s susceptibility to fatigue cracking. Witczak et al. (2002) have shown that dynamic modulus, flow time, and flow number yield promising correlations to field performance.

NCHRP 9-34 is currently looking at the aforementioned tests along with the ECS to develop new test procedures to evaluate moisture damage (Solaimanian et al. 2003). Solaimanian et al. (2006)

reported that the results of the Phase I and Phase II testing of NCHRP 9-34 show that the dynamic complex modulus (DCM) test should be coupled with the ECS for moisture sensitivity testing. This key finding of NCHRP 9-34 (NCHRP Report 589) shows that the ECS/DCM test appears to separate good performing mixes from poor performing mixes in the field when compared with TSR testing from ASTM D 4867 and that the flow number test has high variability, which makes it not recommended for use in moisture-susceptibility testing (Solaimanian et al. 2007). Bausano (2006) used the dynamic modulus test to determine the moisture susceptibility of the mixes at rutting temperature, and the results were good at distinguishing the expected mix behavior. That study recommended trying intermediate and midrange temperatures to study the effect of moisture at those temperatures (Bausano 2006).

2.6 Dynamic Modulus Test

Dynamic modulus is one of the oldest mechanistic tests to be used to measure the fundamental properties of asphalt concrete. Dynamic modulus testing has been studied since the early 1960s by Papazian (1962) and became a standard test in 1979 by the American Society for Testing and Materials (ASTM) under D 3497, "Standard Test Method for Dynamic Modulus of Asphalt Concrete Mixtures" (ASTM 2003). A sinusoidal (haversine) compressive axial stress is applied to a test specimen under the testing procedure for dynamic modulus. The testing procedure includes using various frequencies and temperatures to capture the linear viscoelastic properties of the asphalt concrete.

Dynamic modulus is a measure of the relative stiffness of a mix. Mixes that tend to have good rut resistance at high service temperatures likewise have a corresponding high stiffness. Although the tradeoff is at intermediate temperatures, stiffer mixes are often more prone to cracking in thicker pavements (NCHRP 2004). For this reason, dynamic modulus testing is conducted over a range of test temperatures and frequencies to measure the linear viscoelastic properties of asphalt concrete mixtures. The tested ranges of temperature and frequencies are used to develop a master curve for each mixture in order to exhibit the properties of the mixture over a range of reduced temperatures and/or frequencies. The use of dynamic modulus in moisture-susceptibility evaluation was studied and reported to have good results in NCHRP Report 589 (Solaimanian et al. 2007)

The dynamic complex modulus is determined by applying a uniaxial sinusoidal vertical compressive load to an unconfined or confined HMA cylindrical sample, as shown in Figure 2-1.

Figure 2-1. Haversine loading pattern or stress pulse for dynamic modulus test (Witczak et al. 2002)

The stress-to-strain relationship under a continuous sinusoidal load pattern for a linear viscoelastic material is defined by the dynamic complex modulus, E^* . The dynamic modulus, $|E^*|$, is the absolute value of the dynamic complex modulus. Mathematically, $|E^*|$ is equal to the maximum peak dynamic stress (σ_0) divided by the peak recoverable strain (ϵ_0):

$$|E^*| = \frac{\sigma_0}{\epsilon_0} \quad (2-1)$$

The real and imaginary parts of the dynamic modulus can be written as

$$E^* = E' + iE'' \quad (2-2)$$

Equation (2-2) shows that E^* has two components: a real and an imaginary component. E' is referred to as the storage or elastic modulus component, while E'' is referred to as the loss or viscous modulus. The angle by which the peak recoverable strain lags behind the peak dynamic stress is referred to as the phase angle, ϕ . The phase angle is an indicator of the viscous properties of the material being evaluated.

Mathematically, this is expressed as

$$E^* = |E^*| \cos \phi + i |E^*| \sin \phi \quad (2-3)$$

$$\phi = \frac{t_i}{t_p} \times 360 \quad (2-4)$$

where t_i = time lag between a cycle of stress and strain(s), t_p = time for a stress cycle(s), and i = imaginary number.

For a purely viscous material, the phase angle is 90° , while for a purely elastic material, the phase angle is 0° (NCHRP 465 2002). The dynamic modulus, a measurable “fundamental”

property of an HMA mixture, is the relative stiffness of a mix. Mixes that have a high stiffness at elevated temperatures are less likely to deform. But, stiffer mixes at an intermediate test temperature are more likely to crack in thicker pavements (Shenoy and Romero 2002).

2.7 Dynamic Modulus Master Curves

The asphalt mixtures are thermorheologically simple materials, and the time-temperature superposition principle is applicable in the linear viscoelastic state. The dynamic modulus and phase angle of asphalt mixtures can be shifted along the frequency axis to form single characteristic master curves at a desired reference temperature or frequency that is fitted to a sigmoidal function. The sigmoidal function reaches asymptotically the limiting mix stiffness. At low temperatures, the limiting mix stiffness is dependent on the glassy modulus of the binder, while at high temperatures, the limiting mix stiffness is dependent on the modulus of aggregate skeleton (Pellinen 2008).

Typically the shift factors α_T are obtained from the Williams-Landel-Ferry (WLF) equation (Williams et al. 1955):

$$\log \alpha_T = \frac{C_1(T - T_s)}{C_2 + T - T_s}, \quad (2-5)$$

where C_1 and C_2 are constants, T_s is the reference temperature, and T is the temperature of each individual test.

A new method of developing the master curve for asphalt mixtures was developed in research conducted by Pellinen and Witzak (2002) at the University of Maryland. In this study, master curves were constructed fitting a sigmoidal function to the measured compressive dynamic modulus test data using non-linear least squares regression techniques (Pellinen and Witzak 2002). The shift can be done by solving the shift factors simultaneously with the coefficients of the sigmoidal function. The sigmoidal function is defined by equation (2-6) (Williams et al. 1955).

$$\log |E^*| = \delta + \frac{\alpha}{1 + e^{\beta - \gamma(\log(f_r) + s_T)}}, \quad (2-6)$$

where $\log |E^*|$ = log of dynamic modulus, δ = minimum modulus value, f_r = reduced frequency, α = span of modulus values, s_T = shift factor according to temperature, and β, γ = shape parameters.

2.8 Repeated Load Test (Flow Number) Test

The flow number test (e.g., repeated load test, dynamic creep test) is based on the repeated loading and unloading of an HMA specimen where the permanent deformation of a specimen is recorded as a function of the number of load cycles. The stress applied to the specimen is divided

into two parts: seating stress and deviator stress. The deviator stress is applied for 0.1 second followed by a 0.9 second rest period for the specimen at the seating stress. There are three types of phases that occur during a repeated load test: primary, secondary, and tertiary flow. In the primary flow region, there is a decrease in strain rate with time, followed by a constant strain rate in the secondary flow region, and finally, an increase in strain rate in the tertiary flow region. Tertiary flow signifies that a specimen is beginning to deform significantly and the individual aggregate that makes up the skeleton of the mix is moving past the other “flow.” The flow number is based upon the onset of tertiary flow (or the minimum strain rate recorded during the course of the test) (Robinette 2005). Figure 2-2 graphically shows flow number loading.

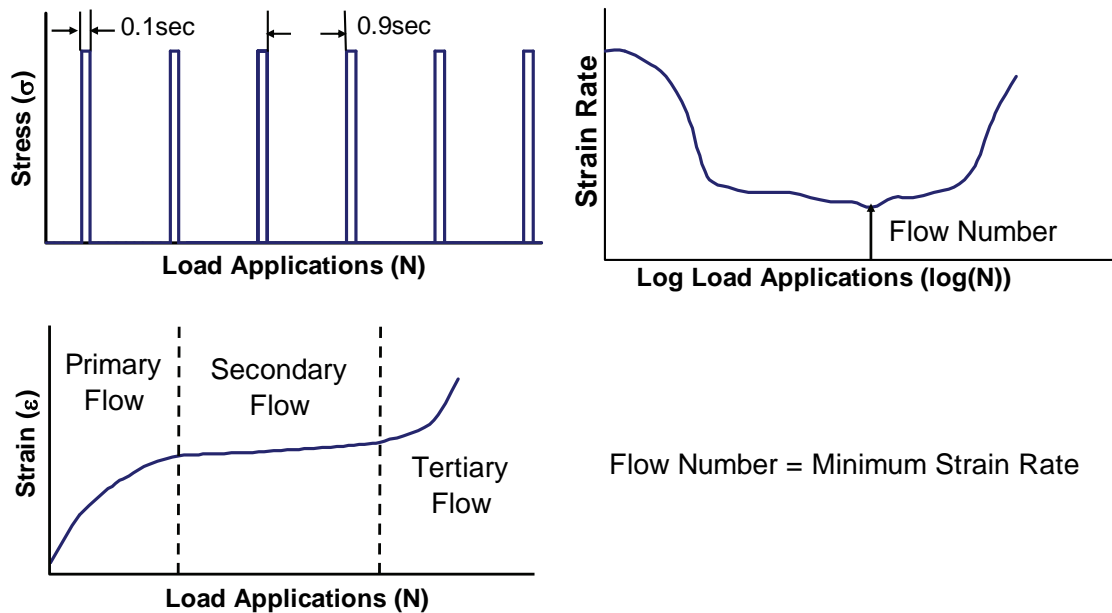

Figure 2-2. Flow number loading (Robinette 2005)

Flow number is defined as the number of load applications when shear deformation begins (Witczak et al. 2002). Flow number testing is similar to pavement loading because pavement loading is not continuous; there is a dwell period between loadings. This dwell period allows a pavement a certain amount of time to recover some strain induced by the loading. There is good correlation between field performance and the flow number. The flow number test could be used as a means of comparing mixes for rut susceptibility (Zhou and Scullion 2003). It was reported in NCHRP Report 589 that flow number test results are not satisfactory when it comes to moisture damage prediction (Solaimanian et al. 2007).

The calculation of flow number was presented in NCHRP report 513. There is a three-step process for flow number calculation. The procedure consists of (1) numerical calculation of the strain rate, (2) smoothing of the creep data, and (3) identification of the minimum smoothed creep rate because this smoothed creep rate is where the flow number occurs. Equation (2-7) was used to determine the creep rate:

$$\frac{d(\varepsilon_p)_i}{dN} = \frac{(\varepsilon_p)_{i+\Delta N} - (\varepsilon_p)_{i-\Delta N}}{2\Delta N}, \quad (2-7)$$

where $\frac{d(\varepsilon_p)_i}{dN}$ = rate of change of strain with respect to cycles or creep rate at i cycle (1/cycle), $(\varepsilon_p)_{i+\Delta N}$ = strain at $i+\Delta N$ cycles, $(\varepsilon_p)_{i-\Delta N}$ = strain at $i-\Delta N$ cycles, and ΔN = number of cycles sampling points.

The next step required that the data be smoothed through a running average of five points. Two creep rates before and after and the creep rate at that instant were used. Equation (2-8) was used to determine the smoothed creep rate:

$$\frac{d\varepsilon'_i}{dN} = \frac{1}{5} \left(\frac{d\varepsilon_{i-2\Delta N}}{dN} + \frac{d\varepsilon_{i-\Delta N}}{dN} + \frac{d\varepsilon_i}{dN} + \frac{d\varepsilon_{i+\Delta N}}{dN} + \frac{d\varepsilon_{i+2\Delta N}}{dN} \right), \quad (2-8)$$

where $\frac{d\varepsilon'_i}{dN}$ = smoothed creep rate at i sec (1/cycles), $\frac{d\varepsilon_{i-2\Delta N}}{dN}$ = creep rate at $i-2\Delta N$ cycles (1/cycles), $\frac{d\varepsilon_{i-\Delta N}}{dN}$ = creep rate at $i-\Delta N$ cycles (1/cycles), $\frac{d\varepsilon_i}{dN}$ = creep rate at i cycles (1/cycles), $\frac{d\varepsilon_{i+\Delta N}}{dN}$ = creep rate at $i+\Delta N$ cycles (1/cycles), and $\frac{d\varepsilon_{i+2\Delta N}}{dN}$ = creep rate at $i+2\Delta N$ cycles (1/cycles)

The final step was to determine the cycle where the minimum creep rate occurs in the data set. If no minimum occurred during the test, then the flow number is reported as being greater than or equal to the number of loads applied during the course of the test. When several minimum creep rates occurred in a data set, the first minimum value is reported as the flow number.

2.9 Ohio State Model

One way to analyze the flow number test results is the Ohio State Model. This model is presented by Huang (2004). It assumes a linear relationship between log the strain and log the number of load repetitions. The formula of this relationship is:

$$\frac{\varepsilon_p}{N} = A(N)^{-m}, \quad (2-9)$$

where ε_p is permanent strain at a specific loading cycle, N is the loading cycle, and A and m are regression constants.

Khedr (1986) analyzed the parameters of this relationship and concluded that the parameter (m) is dependent on the material type. Stress-strain pattern and intensity, stress level, and dissipated plastic strain energy during the dynamic loading affect the parameter (A). The lines achieved are nearly parallel, which means that (m) is constant for all samples of the same material tested under various conditions and is independent of the stress level and temperature, as shown in Figure 2-3. Studying the parameter (A) and applying regression analysis, the result achieved showed that (A) is a function of the applied deviator stress and the resilient modulus.

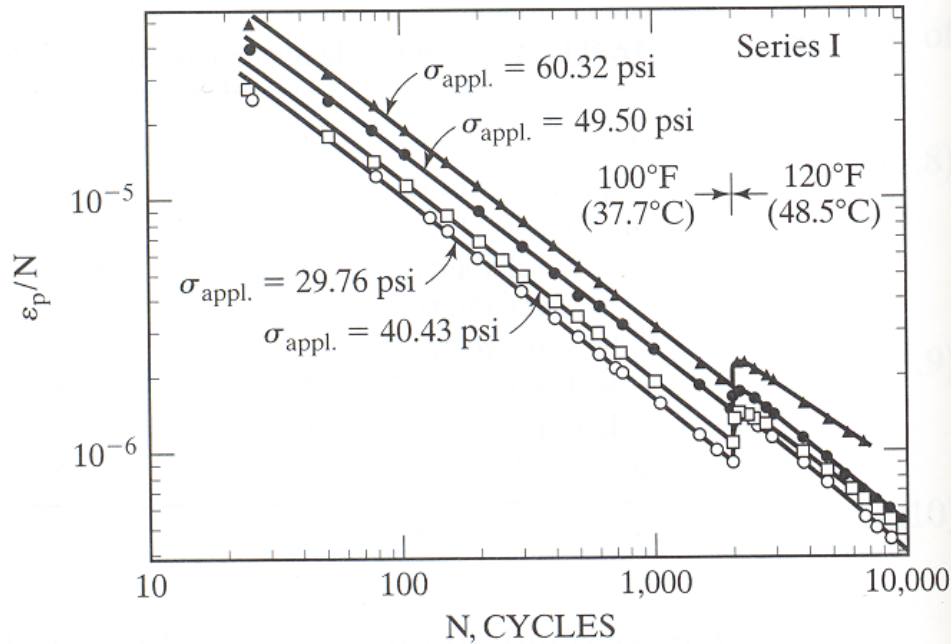

Figure 2-3 Relationship Between ϵ_p/N and N (1 psi = 6.9 kPa), after (Khedr 1986)

The relationship between $\log A$ and $\log (M_R/\sigma_d)$ is a straight line, as shown in Figure 2-4 and represented by equation (2-10) (Khedr 1986).

$$A = a \left(\frac{M_R}{\sigma_d} \right)^{-b}, \quad (2-10)$$

where A is the regression constant from equation (2-9), M_R is the resilient modulus, σ_d is the applied deviator stress, and a and b are material-dependent regression constants.

Majidzadeh et al. (1979) applied these two relationships. They tested specimens by varying the deviator stress and the temperature. The variation in parameter (m) came out to be insignificant. They generalized the results by taking an average value for (m), which represents the all tested samples, and then calculated the normalized value of the parameter (A). The relationship shown in equation (2-10) was analyzed using the normalized (A) value, and both equations came out to be applicable to all samples tested in that research.

Figure 2-4. Relationship between parameter A and M_R/σ_d , after (Khedr 1986)

3. EXPERIMENTAL PLAN AND TEST SETUP

3.1 Experimental Plan

Loose samples were procured from 16 projects that were constructed within the state of Iowa. A summary of job mix formulas is presented in Appendix A. The mixes were selected to cover a wide range of material properties. The samples included base coarse, intermediate coarse, and surface coarse mixes. Three traffic levels were considered: less than 3 million equivalent single-axle loads (ESALs), 3 to 10 million ESALs, and greater than 10 million ESALs. Two nominal maximum aggregate sizes (NMAS)—12.5 and 19.0 mm—were used, and three binder performance grades (PG 58-25, PG 64-22, and PG 70-28) were represented. The properties of the mixes are presented in Table 3-1.

Table 3-1. Properties of sampled mixes

Project Name	NMAS (mm)	Binder PG	Traffic Level	Designation
			Million ESALs	
HWY 330 Base	19.0	64-22	<3	330B
HWY 218, Tripoli	19.0	64-22	<3	218
I-80 Base	19.0	64-22	>10	I80B
I-235 Intermediate	19.0	70-28	>10	235I
6th St. Nevada	12.5	64-22	<3	6N
Dedham	12.5	58-28	<3	Ded
Rose Street	12.5	64-22	<3	Rose
F-52	12.5	58-28	<3	F52
Northwestern Avenue	12.5	64-22	<3	NW
HW 4	12.5	58-28	<3	HW4
HWY 330 Int.	12.5	64-22	3-10	330I
Jewell	12.5	64-22	3-10	Jewell
HWY 330 Surface	12.5	64-22	3-10	330S
I-80 Surface	12.5	64-22	>10	I80S
I-235 Surface	12.5	70-28	>10	235S
Altoona	12.5	64-22	>10	ALT

The samples were compacted using a Pine Superpave gyratory compactor to obtain samples that were 100 mm in diameter and approximately 150 mm in height. All samples were compacted to $7\% \pm 1\%$ air voids. The experimental plan was developed to be able to test the samples under different conditions that might occur in the field. The samples were subjected to five different modes of moisture conditioning: (1) unconditioned without water submersion testing, (2) unconditioned with water submersion testing, (3) moisture saturation with water submersion testing, (4) moisture saturation with freeze/thaw conditioning without water submersion testing, and (5) moisture saturation with freeze/thaw conditioning and with water submersion testing. Five replicates were tested in each condition for each mix. The five conditions were tested under the flow number test scheme. Condition 2 was only tested on 5 of the 16 mixes. It was not

possible to run the dynamic modulus test in the case of water submersion because the test protocol dictates the use of external linear variable differential transformers (LVDTs) on the sides of the specimen. As a result, the dynamic modulus test was performed on unconditioned samples (condition 1) and samples conditioned with one freeze-thaw cycle (condition 4). The test was performed at two different temperatures (4°C and 21°C) and nine frequencies (0.1, 0.3, 0.5, 1.0, 3.0, 5.0, 10.0, 15.0, and 25.0 Hz). The samples used in the dynamic modulus testing were then used in the flow number testing. Ten samples, not five, were tested in condition 4 because the samples were used in conditions 4 and 5 for flow number testing. Ten gyratory-compacted samples 100 mm in diameter and 62.5 mm in height with 7% ± 1% air voids. The samples were split into two groups with equal average air voids. One of the groups was used as a control, and the second group was conditioned with one freeze/thaw cycle (condition 4). Table 3-2 summarizes the testing plan, where each X represents a sample tested.

Table 3-2. Samples tested at the different conditions

Test	Condition 1	Condition 2*	Condition 3	Condition 4	Condition 5
Dynamic Modulus	XXXXX			XXXXX XXXXX	
Flow Number	XXXXX	XXXXX	XXXXX	XXXXX	XXXXX
AASHTO T283	XXXXX			XXXXX	

* This condition was applied to five mixtures only.

3.2 Sample Conditioning

The conditioning of the samples was done in accordance to AASHTO T 283, “Resistance of Compacted Bituminous Mixture to Moisture Induced Damage.” Specimens were compacted according to section 4.2.3 in AASHTO T 283 and divided into two subsets so that each subset had the same average air voids. The dry subset (control group) deviated from the standard specification as the samples were placed in an environmental chamber rather than being wrapped with plastic or placed in a heavy-duty, leak-proof plastic bag and stored in a water bath at 25°C ± 0.5°C for two hours ± ten minutes prior to testing. The conditioning of the conditioned subset specimens was done by placing the samples in a pycnometer with a spacer. Approximately 25 mm of water was placed above the specimen. The specimen was vacuum saturated for five to ten minutes at 13–67 kPa. The specimen was left submerged in water bath for five to ten minutes after vacuum saturating. The mass of the saturated, surface-dry specimen was determined after partial vacuum saturation. Next, the volume of absorbed water was calculated. Finally, the degree of saturation was calculated. If the degree of saturation was between 70% and 80%, testing proceeded. If the degree of saturation was less than 70%, the vacuum saturation procedure was repeated. If saturation was greater than 80%, the specimen was considered damaged and discarded. If the sample required a freeze/thaw cycle, each vacuum saturated specimen was tightly covered with plastic wrap and placed in a plastic bag with approximately 10 ± 0.5 ml of water and sealed. The plastic bags were then placed in a freezer at -18°C ± 3°C

for a minimum of 16 hours. After the freeze/thaw cycle, the final steps were the same for moisture conditioning with or without freeze/thaw cycling. The next step was to place the samples in a water bath at $60^{\circ}\text{C} \pm 1^{\circ}\text{C}$ for 24 ± 1 hour with 25 mm of water above the specimens. The specimens were then removed and placed in a water bath at $25^{\circ}\text{C} \pm 0.5^{\circ}\text{C}$ for two hours \pm ten minutes. Approximately 25 mm of water should be above the specimens. Not more than 15 minutes should be required for the water bath to reach $25^{\circ}\text{C} \pm 0.5^{\circ}\text{C}$. If needed, ice could be used to prevent temperature increase. The specimens were then ready for testing.

3.3 Dynamic Modulus Test

The test setup was derived from NCHRP Report 547 (Witczak 2005). The test was performed using a universal servo-hydraulic testing system inside a temperature-controlled environmental chamber that was set to the designated test temperature. The test was a strain-controlled test, in which the strain was maintained at 80 microstrain to be able to capture the linear viscoelastic behavior of the material. The vertical deformation measurements were obtained using four LVDTs with a 100 mm gage length. They were attached to the specimen by aluminum buttons, which were fixed on the specimen surface using epoxy glue. One average strain measurement was obtained from the four LVDTs, and this average strain was then used to control the test. The test setup is shown in Figure 3-1.

Figure 3-1. Dynamic modulus test setup (NCHRP Report 547)

The test was performed at two different temperatures (4°C and 21°C) and nine frequencies (0.1, 0.3, 0.5, 1.0, 3.0, 5.0, 10.0, 15.0, and 25.0 Hz). At each frequency-temperature combination, the dynamic modulus value and the phase angle were calculated. The concept of time-temperature superposition was applied to the results from these temperatures and frequencies to develop a master curve for each mix. The master curve can be used to predict the modulus at other temperatures and frequencies. The use of more frequencies and less temperatures is more practical because it reduces the testing time.

3.4 Flow Number Test

The testing procedure described herein was derived from NCHRP Report 465 (Witzack et al. 2002) and NCHRP Report 513 (Bonaquist et al. 2003). This testing protocol has been referred to as Protocol W1: Simple Performance Test for Permanent Deformation Based upon Repeated Load Test of Asphalt Concrete Mixtures.

A 100 mm diameter by 150 mm high cylindrical specimen was tested under a repeated haversine compressive stress at a single effective temperature unconfined. A UTM 14P machine was used to conduct the tests with a temperature-controlled testing chamber. The load was applied for a duration of 0.1 sec and a dwell period of 0.9 sec. No design axial stress levels have been stipulated in the NCHRP 465 or 513 protocols. The deviator stress used in testing the 16 mixtures was 600 kPa (87 psi), which is analogous to the load used in the Superpave gyratory compactor. Since no confining pressure was used, the axial stress is the deviator stress stated (600 kPa). The effective test temperature was selected to be 37°C, which is representative of the effective rutting temperature in the state of Iowa. The temperature inside the environmental chamber was checked using a probe inserted in a dummy sample. The strains for these tests were measured directly through the machine's actuator as opposed to affixing axial LVDTs to the sides of the specimen. Affixing axial LVDTs to the side of the specimen is not suitable to the test conditions because of the high deformation levels expected during the test.

Specimens were placed in the testing chamber for a minimum of two hours, as specified in Protocol W1, to ensure that the test temperature was obtained in the test specimens. After the test temperature had been reached, the specimen was centered under the loading platens so as to not place an eccentric load on the specimen. The test was conducted in accordance with the aforementioned parameters. Depending on the test condition designated for the sample, the sample was either placed in water or not. The water in the container was at the designated test temperature. The test setup is shown in Figure 3-2.

Figure 3-2. Flow number test setup

The loading regime was applied to the specimens for a total of 40,000 continuous cycles or until the specimen failed and resulted in excessive tertiary deformation, whichever occurred first. Excessive deformation was considered 100,000 microstrain. The exact length of the test was variable from one mixture to the next because of the different material properties.

3.5 Indirect Tensile Strength Testing

The testing procedure described herein is derived from the AASHTO T 283, “Resistance of Compacted Bituminous Mixture to Moisture Induced Damage.” The indirect tensile strength of the dry and conditioned specimens was determined at 25°C. The specimen was placed between two bearing plates in the testing machine such that the load was applied along the diameter of the specimen, as shown in Figure 3-3. A universal testing machine was used to conduct the testing.

Figure 3-3. Indirect tensile strength test setup

The load was applied at a constant rate of movement of the testing machine head of 50 mm per minute. The maximum load was recorded and placed in the equation (3-1) in order to calculate tensile strength.

$$S_t = \frac{2000 \times P}{\pi \times t \times D}, \quad (3-1)$$

where S_t = tensile strength (kPa), P = maximum load (N), t = specimen thickness (mm), and D = specimen diameter (mm).

A numerical index or resistance of an HMA mixture to the effects of water is the ratio of the original strength that is retained to that of the moisture conditioned strength.

$$TSR = \frac{S_2}{S_1}, \quad (3-2)$$

where TSR = tensile strength ratio, S_2 = average tensile strength of conditioned subset, and S_1 = average tensile strength of dry subset.

4. DYNAMIC MODULUS TEST RESULTS AND ANALYSIS

4.1 Approach

The dynamic modulus was performed on two groups of samples: control and moisture-conditioned samples. The dynamic modulus values and phase angles were calculated for the mixes at the different frequency-temperature combinations. The approach of this analysis was to evaluate the change of dynamic modulus and its associated parameters (phase angle, storage modulus, and loss modulus) and see which of these parameters is linked directly to moisture damage. A visual representation of the results is presented by plotting the master curves for the different mixes for both the control and conditioned groups.

4.2 Dynamic Modulus Test Results

The results of the dynamic modulus test and phase angle for both the control and conditioned groups are presented in Appendix B. The E^* ratios were then calculated by dividing the dynamic modulus results from the moisture conditioned group by those from the control group (see Table 4-1). The lower the E^* ratio, the greater the effect of moisture conditioning on a specific mix. The E^* ratios appear to vary with test temperature and frequency. The general trend is that the E^* ratio decreases with an increase in temperature and/or a decrease in frequency. This variation provides the impetus for performing a statistical analysis to check the variability in the results. The phase angle ratios are presented in Table 4-2. The increase in the phase angle ratio indicates greater moisture damage. The general trend is that the phase angle values increase with moisture conditioning. This means that the moisture-conditioned samples are more viscous compared to the control samples. The phase angle ratio decreases with the decrease in test frequency and an increase in test temperature.

4.3 Statistical Analysis

A statistical analysis was performed to test the hypothesis that the results at different temperature-frequency combinations are statistically different. A pairwise comparison using a level of significance (α) of 0.05 was performed between the ratios for the 16 mixes at each of the temperature-frequency combinations to those at the other frequency-temperature combinations. The results of this statistical analysis are presented in Table 4-3 and show that there are statistical differences between the results. This means that the temperature and the loading frequency are significant factors and that they affect the extent of moisture damage to which the mix is subjected. The same analysis was performed on the phase angle ratio (see Table 4-4). The analysis also showed that many of the temperature-frequency combinations are statistically different from the other combinations.

Figures 4-1 and 4-2 show the E^* ratio distribution for all the mixes with respect to temperature and frequency, respectively. It appears from Figure 4-1 that the range of ratios at 21°C is larger than that at 4°C. The Tukey-Kramer all pairwise comparison method was used to test whether the mixes are statistically different from each other. This was used to group the mixes that show no statistical difference from each other. The results of the comparison are presented in Tables 4-5 and 4-6 for the E^* ratio and phase angle ratio results, respectively. Ranking the mixes at the different temperature-frequency combinations using E^* ratios is presented in Table 4-7, while combinations using phase angle ratios are presented in Table 4-8.

4.4 Master Curves

The data from the dynamic modulus test was used to plot master curves for the different mixes. For each mix, the master curve for the control and moisture-conditioned results are plot together at a reference temperature of 21°C. Figures 4-3 through 4-16 present the master curves for the 16 mixes. It can be seen from the master curves that at low temperature and/or high frequencies, the moduli for the control and moisture-conditioned samples are very close for all the mixtures, with a possible increase in the dynamic modulus values for the moisture-conditioned group. The values of the moduli start to be different when the temperature is increased and/or the frequency

is decreased. The magnitude of the difference changes from one mixture to the other, depending on the moisture susceptibility of the mixes. This means that developing the master curves provides a good means to visualize the effect of moisture on the mixes over the full range of the operating frequencies and temperatures. Only 1 of the 16 mixtures (330S) did not follow this trend—the moisture-conditioned sample’s modulus increased at higher temperatures and/or lower frequencies.

For the mixes studied under this project, the area under the master curve was calculated to quantify the difference caused by moisture conditioning. Based on the previous discussion, the area under the master curve had to be split into two zones. The first zone is for frequencies lower than 10 Hz at the reference temperature, which represents the high-temperature–low-frequency zone. The second zone is for frequencies higher than 10 Hz, which represents the low-temperature–high-frequency zone. The results are shown in Table 4-9. The results show that splitting the area under the master curve can be used to provide a good distinction between the different mixes when it comes to moisture susceptibility. The distinction is very clear at the high-temperature–low-frequency zone.

4.5 Storage and Loss Moduli

The dynamic modulus and phase angle were used to calculate the storage and loss moduli for all the mixes. The storage modulus ratio is the storage modulus of the control mix divided by that of the moisture conditioned mix. Table 4-10 presents the storage modulus ratios for all the

temperature-frequency combinations. The same was done for the loss modulus, and the results for the loss modulus ratios are presented in Table 4-11. The results of the storage modulus ratios show that although the ratios have a trend within the same mix, there is no specific trend between the mixes. The ratios are sometimes higher than one and sometimes lower, and this result makes these values inconclusive when it comes to the effect on the mix performance. For the case of the loss modulus ratios, the results do not have a specific trend within the mixes.

4.6 Comparison between E* Ratio and Master Curve

A paired t-test was used to compare the significance of the difference between the dynamic modulus results of the conditioned and the unconditioned group. A similar comparison was done to compare the difference between the master curves of both groups. The results of both comparisons are presented in Table 4-12, with a level of significance (α) = 0.05. The results show that the two methods yield different conclusion.

Table 4-12. Statistical comparisons for E* and master curves

4.7 Dynamic Modulus Test Conclusions

The dynamic modulus ratio gives a good evaluation for the moisture susceptibility of the mixes. It provides a distinction between the mixes, and the results can be used in modeling the mix performance. The E* ratio results are dependent on the testing conditions (temperature and frequency). This means that the results from the dynamic modulus test need to be coupled with some evaluation tool related to the expected in situ conditions of the pavement. This means that simulation is necessary in this case. This can be done either by modeling or by simulating the results in the MEPDG. Another easy approach that can be used is to plot the master curve of the control and conditioned groups and then compare the results to have a visual representation of the effect of moisture on the various working conditions. The area under the master curve can be used to quantify the effect of moisture damage provided that a range of frequencies be selected to reflect the expected site conditions for the pavement. The phase angle ratios show that the materials tend to be more viscous with moisture conditioning. The storage and loss moduli ratios are not recommended as tools to evaluate moisture damage because of the scatter in the data and the mixed results.

5. FLOW NUMBER TEST RESULTS AND ANALYSIS

5.1 Test Results

In this chapter, the flow number results are presented and discussed. As mentioned earlier in the experimental plan, the test followed the NCHRP Report 465 (Witczak et al. 2002) and NCHRP Report 513 (Bonaquist et al. 2003) procedure and calculation method. The calculation method was discussed in the literature review. The flow number test is known for its variability. The test is also known to be a good representation of the field's loading conditions. Good simulation of the field loading conditions was the reason for including this test in this study. Several outputs, other than the flow number, can be calculated from this test. The number of cycles at which the test stops, the total strain at the end of the test, the flow number, and the strain at the flow number are general outputs that can be calculated from this test. These results are shown in Tables 5-1 through 5-5. By looking at the results, the following can be concluded. The number of cycles at which the test ends is not a reliable measure because it occurs either by the specimen failure or by reaching the machine test limit, which is 40,000 cycles. The strain at failure is constant when the sample reaches failure. The flow number is the main output of this test, and it can be seen that this output has very high variability. The same is true for the strain at flow number.

The previous discussion leads to the need to have a different analysis method for the test. Two approaches were incorporated in this study. The first approach was to have a designated strain level and to get the corresponding number of cycles. A strain level of 30,000 microstrain was selected for this purpose. The second approach was to apply the Ohio State Model on the test results and see if the parameters A and m are affected by moisture conditioning or not. Parameter m was primarily taken into consideration because this parameter is a function of the material properties as discussed in the literature review.

It can be concluded from Tables 5-1 through 5-5 that the parameters tested (cycles to failure, flow number, cycles at 30,000 microstrain, and parameter *A*) have very high variability. Parameter *m* has lower variability compared to the other parameters. Tables 5-6 through 5-9 present the ratio of dividing the different parameters at each condition by those of the control samples. It should be noted that the strain at flow number and parameter *A* are expected to increase with moisture conditioning, so the ratios are expected to be greater than one.

5.2 Statistical Analysis

The parameters studied in the flow number test showed very high variability represented in the coefficient of variation. The parameter that showed the least variability in most of the cases is the parameter m . Cycles to failure will not be included in the statistical analysis because cycles to failure are based on two different failure conditions caused by the machine limit, which introduced extra variability to this parameter. The flow number ratios are scattered around one, which provides inconclusive results. The variability in the flow number ratios is shown in Figure 5-1 for one of the conditions—the freezer-conditioned samples tested in air. This variability is similar to what was found by Solaimanian et al. (2007). Strain at flow number followed a similar trend, as shown in Figure 5-2. Both parameters A and m offer promising results, but only parameter m will be considered because it depends mainly on the material properties and the ratios achieved using this parameter are very consistent in being less than one, except for one reading that was 1.29.

6. AASHTO T 283 TEST RESULTS

Performing the AASHTO T 283 test is important to compare the results achieved using the other methods to those achieved using the AASHTO T 283 test. The main reason behind the comparison is that AASHTO T 283 is what practitioners are used to performing and thus provides a good reference to the test that is currently being used in practice. The test followed the methodology described in Chapter 3. Two groups of samples were tested: a control group and a moisture-conditioned group, which was subjected to one freeze/thaw cycle. Five samples were tested in each group. Table 6-1 presents the tensile strength for both groups for the mixes tested. The individual sample results are presented in Appendix C. The results were then used to calculate the TSR, which is presented in Table 6-2. The TSR was used to rank the mixes, where 1 represents the least moisture-susceptible mix. The ranking of the mixes is presented in Table 6-2. The next step was to perform a statistical analysis on the results. A statistical analysis software (JMP) was used in the analysis. The first hypothesis that was tested was that the mean of the two tested groups for all the mixes was equal. This hypothesis was tested by a pairwise comparison t-test. This resulted in a p-value of less than 0.0001, which means that the hypothesis is rejected at a level of significance $\alpha = 0.05$ and that the two groups are statistically different. The second hypothesis that was tested was that the mean of the two groups for each mix is equal for the five samples tested for this mix. The results of this analysis are presented in Table 6-2. The results are presented as a p-value and whether the two means are statistically different. It can be seen from the results of this analysis that the means of the good performing mixes are not statistically different (p-value less than 0.05). It appears that the transition between the statistically similar and the statistically different groups occurs somewhere between TSR values of 0.93 and 0.86.

7. COMPARISON BETWEEN THE DIFFERENT TEST METHODS

In order to investigate the difference in results between the three tests investigated, the results achieved using the different tests were compared. The results from the three tests were compared together. The comparisons were done between samples with the same conditions. This means that only samples tested under condition 4 (moisture-conditioned with one freeze/thaw cycle) and condition 1 (control) were included in this comparison. Based on the discussion presented earlier about the dependence of the E^* ratio on temperature and frequency, a situation corresponding to that of the flow number was considered. The master curves were used to calculate the dynamic modulus at 37°C and a loading frequency of 10 Hz. These dynamic modulus values were then used to calculate the ratios used in the statistical analysis. The average of the E^* ratios of all the tested temperature-frequency combinations was also used in the comparison. A statistical analysis software (JMP) was used to run a statistical analysis to show statistically different groups. The comparison was done for the ratio between the conditioned and unconditioned group results. The results of the different tests are presented in Table 7-1. A paired t-test comparison was performed on these results. The results of the comparison are presented in Table 7-2. The results showed that there is no statistical difference between the parameter m and the TSR ratio and the average E^* ratio. All the other comparisons are statistically different. Figures 7-1 through 7-6 show a graphical representation for the tested pairs. The ranking of the mixes based on the different methods is presented in Table 7-3.

Table 7-1. Results from different tests

8. CONCLUSIONS AND RECOMMENDATIONS

In this research, 16 mixes were collected from the state of Iowa. The mixes were selected to cover a wide variety of materials and traffic levels. For each mix, samples were compacted using a Superpave gyratory compactor and were divided into four groups with equal average air voids and different conditioning/testing schemes. Five of the mixes were subjected to a fifth conditioning/testing scheme. Dynamic modulus, flow number, and TSR (AASHTO T 283) tests were performed on the samples. The results were statistically compared.

8.1 Conclusions

Based on the range of materials and the parameters tested in this research, the following can be concluded:

- The dynamic test is sensitive to the effect of moisture on the mixture. The extent by which the dynamic modulus value is affected due to the moisture conditioning is impacted by the temperature and the loading frequency. This means that the effect of moisture varies by the loading conditions.
- For the dynamic modulus results, the effect of moisture appears more with higher temperatures and/or lower frequencies.
- For best results, the dynamic modulus test results need to be combined either with information about the conditions at which the mix is going to be used or with a tool that helps visualize the effect of temperature over a range of temperatures and frequencies.
- Plotting a master curve provides a good tool to visualize the effect of moisture on the mix.
- All the parameters evaluated from the flow number test results gave mixed results, except for the parameter m , which provided consistent results.
- There is no evidence of a statistical difference between the ratios calculated using the average E^* values and the indirect tensile test when compared to parameter m .
- The different conditioning schemes used in conjunction with the flow number test showed no evidence of statistical difference. The effect of the different conditioning schemes of the mixes on the flow number results varied from one mix to the other, and this variability makes them inconclusive. These results can be attributed to the variability of the flow number test. Alternative methods of examining flow number data need to be considered, such as accumulated strain at a prescribed number of load cycles.

8.2 Recommendations

Based on the results of this research, the following suggestions are recommended:

- Try the various testing/conditioning with the dynamic modulus test by using LVDTs that can be tested under water or by using the actuator LVDT, which might reduce the accuracy of the results.

- Run the dynamic modulus test only and skip the flow number test. This gives a chance to moisture condition the sample after running the control test, and then the sample can be tested again. This approach will reduce the variability introduced by testing two sets of samples.
- The dynamic modulus results should be related to the operating conditions.
- The use of parameter m calculated from the flow number test eliminates the need to test the sample to failure because the sample does not need to reach the tertiary flow to calculate this parameter.
- Monitoring the field performance of the mixes and comparing it to the laboratory results is very important to judge the quality of the test results and to judge which test provides the most accurate results.

APPENDIX B. DYNAMIC MODULUS TEST RESULTS

The results of the dynamic modulus test and phase angle for the control group are presented in Tables B-1 and B-2, respectively. The results for the conditioned group are presented in Tables B-3 and B-4.
